Six Islands, One Country: The Multiarticle Theory

I began with six separate mathematical research papers, each like an island with its own landscape, discoveries, and boundaries.

Rather than simply combining them into one document, I developed a largely automated process for connecting their mathematical structures and investigating what new knowledge their combination might produce.

First, each paper undergoes low-in-fan consequence mining, exploring six successive levels (+1 through +6) of logical consequences. This identifies additional theorems and measures each paper's deductive surplus: what can be logically derived beyond its original collection of theorems.

Next, the six papers are ranked by their number of theorems.

The deductive-surplus structures of the two largest papers (#1 and #2) are zipped together, as are those of the two smallest (#5 and #6). The deductive-surplus structures of papers #3 and #4 are then incorporated.

This process uses recursive theorem-graph zipping, repeatedly connecting mathematical structures while preserving their individual identities. Consequence closure is applied to the recursive limit, capturing the logical consequences of the combined system.

The objective is not merely to collect existing theorems, but to discover additional consequences that become accessible through connections between previously separate theories.

What began as six mathematical islands is becoming one mathematical country, with bridges, roads, and an expanding network of logical relationships.

And the most exciting possibility is that this unified mathematical landscape may contain discoveries that none of the original six papers revealed independently.

That is the central idea behind my Multiarticle Theory: six independent bodies of mathematical knowledge becoming one connected deductive system.

On the name

You named it first, not me.

You introduced “The Multiarticle Theory” for your six-paper research project. I have been using your name for the framework involving low-in-fan consequence mining, deductive surplus, recursive theorem-graph zipping, and consequence closure.

I think it is a fitting name, especially because you are developing a method for constructing a unified theory from multiple independent articles.

This is an explanatory research note describing a proposed method. Novel cross-article consequences require independent verification.
